

Chapter 8: Switching

Outline

8.1 INTRODUCTION

8.2 CIRCUIT-SWITCHED NETWORKS

8.3 PACKET-SWITCHING

8-1 INTRODUCTION

A network is a set of connected devices. Whenever we have multiple devices, we have the problem of how to connect them to make one-to-one communication possible. The solution is switching.

A switched network consists of a series of interlinked nodes called switches. Switches are devices capable of creating temporary connections between two or more devices linked to the switch.

Figure 8.1: Switched network

Switches I, II, III, IV, V are devices capable of creating temporary connections between two or more devices linked to the switch.

8.1.1 Three Methods of Switching

*Traditionally, there are three methods of switching: **circuit switching**, **packet switching** and **message switching**. Packet switching can further be divided into two subcategories: datagram approach and virtual-circuit approach.*

8-2 CIRCUIT-SWITCHED NETWORKS

A circuit-switched network consists of a set of switches connected by physical links, in which each link is divided into n channels.

A connection between two stations is a dedicated path made of one or more links. Each connection uses a dedicated channel on each link. Each link is normally divided into n channels by using FDM or TDM.

Figure 8.3: *A trivial circuit-switched network*

In circuit switching, the resources need to be reserved during the setup phase. The resources remain dedicated for the entire duration of the data transfer phase until the teardown phase.

8.2.1 Three Phases

*The actual communication in a circuit-switched network requires three phases: (1) **connection setup**, (2) **data transfer** and (3) **connection teardown**:*

*(1) **Connection Setup**: Before the entities can communicate, a dedicated circuit needs to be established. Note that end-to-end addressing (e.g., telephone numbers) is required for creating a connection between the two end systems.*

*(2) **Data Transfer**: After the establishment of the dedicated circuit, the two entities can transfer data.*

*(3) **Connection Teardown**: When one of the entities needs to disconnect, a signal is sent to each switch to release the resources.*

8.2.2 Efficiency

Efficiency: It can be argued that circuit-switched networks are not as efficient as packet- or message-switched networks since resources are allocated for the entire duration of the connection; and unavailable to other connections. Let's consider the following 2 scenarios for comparison:

(a) In a telephone network, people normally terminate the communication when they have finished their conversation.

(b) In a computer network, a computer can remain connected to another computer even if there is no activity for a long time → other connections are deprived.

Figure 8.6: Delay in a circuit-switched network

While a circuit-switched network normally has low efficiency, the delay is minimal. During data transfer, the data are not delayed at each switch as the resources are allocated for the duration of the connection.

$$\text{Total delay} = \text{Setup time} + \text{Data transfer Time} + \text{Teardown time}$$

Example

Consider a circuit-switched network that connects computers in two remote offices of a private company. The offices are connected using a T1 line leased from a communication service provider. There are two 4×8 (4 inputs, 8 outputs) switches in this network.

Solution

For each 4×8 switch, four output ports are folded back into the input ports to allow communication between computers in the same office. The other four output ports allow communication between the two offices as shown below:

8-3 PACKET SWITCHING

In data communications, we need to send messages from one end system to another. If the message is going to pass through a packet-switched network, the message needs to be divided into packets of fixed or variable size (size of the packet is determined by the network and the governing protocol).

In packet switching, there is no resource reservation for a packet: no reserved bandwidth on the links, no scheduled processing time for each packet. Resources are allocated on-demand on a first-come, first served (FCFS) basis.

8.3.1 Datagram Networks

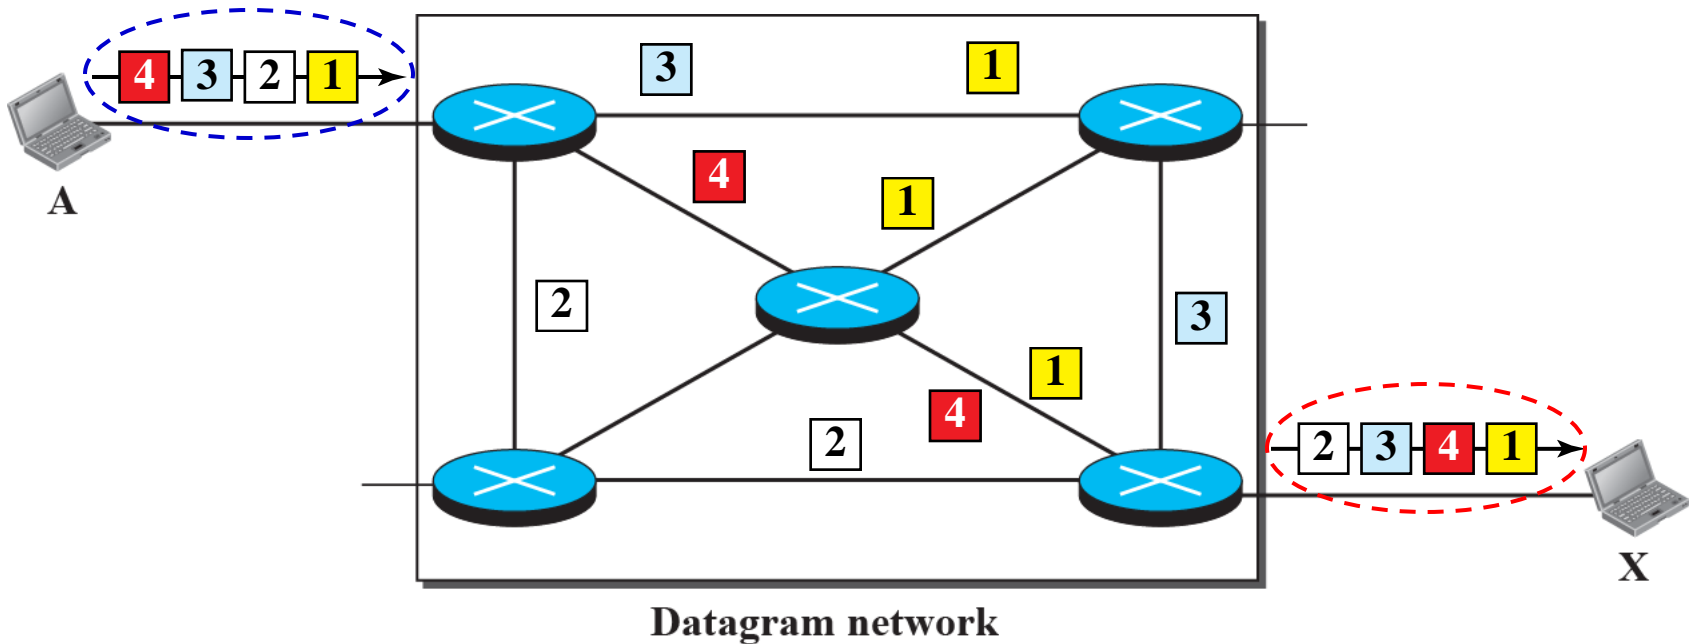

*We have two types of packet-switched networks: **datagram networks** and **virtual-circuit networks**.*

*In a **datagram network**, each packet is treated independently of all others. Even if a packet is part of a multipacket transmission, the network treats it as though it existed alone. Packets in this approach are referred to as datagrams.*

Datagram switching is normally done at the network layer (note that the term “switching” is not exclusively referencing only layer 2 “switches”).

Figure 8.7: A Datagram network with four switches (routers)

Example of datagram switching to deliver four packets from A to X. All four packets belong to the same message, but may travel different paths from A to X.

Datagram networks are sometimes referred to as connectionless networks. The term *connectionless* means that the switch does not keep information about the connection state: each packet is treated the same by a switch regardless of its source or destination.

Figure 8.8: Routing table in a datagram network

The destination address in the header of a packet in a datagram network remains the same during the entire journey of the packet.

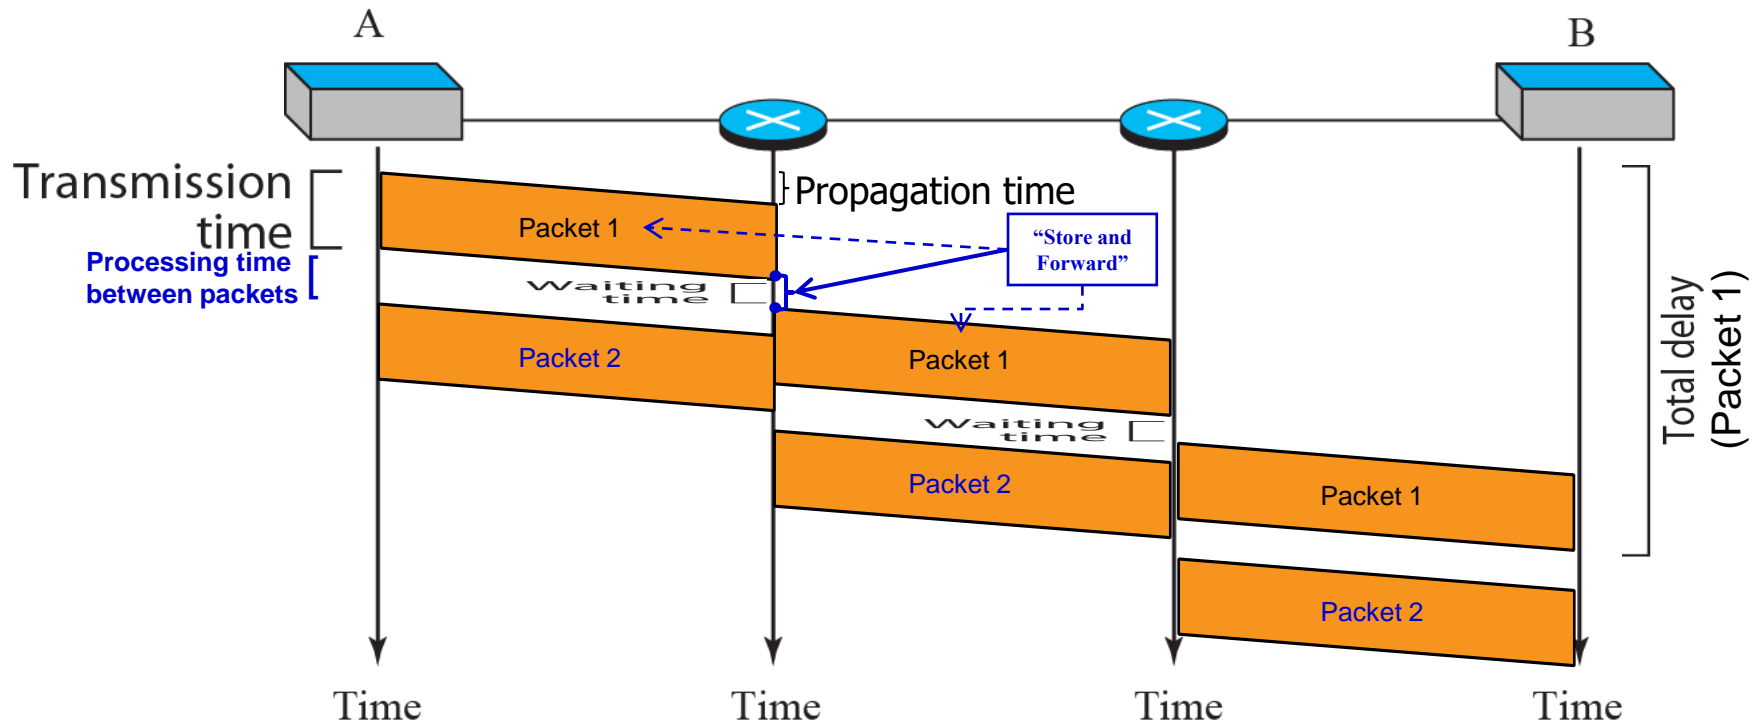

A switch in a datagram network uses a routing table (based on the destination address) where the destination addresses and corresponding forwarding output ports are recorded.

The routing tables are dynamic and updated periodically.

Figure 8.9: Delays in a datagram network

Efficiency of a datagram network is better than that of a circuit-switched network as resources are allocated only when there are packets to be transferred. However, there may be longer delays in a datagram network as each packet may experience a wait time at each switch before being forwarded. In addition, the delay may not be the same for all packets.

$$\text{Total delay}_{(\text{Packet 1})} = 3 \times \text{Transmission time} + 3 \times \text{Propagation time} + 2 \times \text{Waiting time}$$

(Note that the transmission, propagation and waiting times may not be the same at each switch)

8.3.2 Virtual-Circuit Networks

A *virtual-circuit network* is a cross between a circuit-switched network and a datagram network. It has some characteristics of both:

- 1) There are setup and teardown phases in addition to the data transfer phase (circuit-switched).
- 2) Resources can be allocated during the setup phase (circuit-switched) or on-demand (datagram).
- 3) Data are packetized (datagram) but address in header only has local jurisdiction, i.e., only knows next switch/channel, not end-to-end jurisdiction.
- 4) All packets follow the same path established during the connection (circuit-switched)
- 5) Normally implemented in the data link layer. (Physical layer: circuit-switched; Network layer: datagram)

Figure 8.16: Delay in a virtual-circuit network

In virtual-circuit switching, all packets belonging to the same source and destination travel the same path. Resource reservation can be made during the setup phase or on-demand during the data-transfer phase. The delay for each packet is the same for the former and may be different for the latter.

Total delay = Setup time + 3 x Transmission time + 3 x Propagation time + Teardown time

(Assumption: resource reservation is made during the setup phase, otherwise include additional delay for individual packets at each switch)
